## Higher categories & Wittgenstein's ladder

My propositions elucidate in the sense that anyone who understands me will eventually recognize them as nonsense, once they have climbed through them – on them – beyond them. (They must, as it were, throw the ladder away after they have climbed up it.) They must surmount these propositions; then they will see the world aright.

---

– Ludwig Wittgenstein, *Tractatus Logico-Philosophicus*, 6.54.

We cannot yet give a thorough and precise account of higher category theory in the same terms that experienced practitioners use it. Instead, we have to construct a *model* of higher categories within established set-theoretic foundations. We will then work within that model to develop a slate of fundamental definitions, constructions, and theorems. Once enough of this development is complete, the corresponding *higher category of higher categories* is then unique. At that point, we are free to ignore the set-level specifics of the chosen model and to work contentedly in a natively higher-categorical way.

This process of abstraction permeates mathematics. For example, according to set theory, the number 3 might refer to:

- a set with 3 elements (when viewed as a natural number),
- a set with countably many elements (when viewed as an integer or as a rational number), or
- a set with uncountably many elements (when viewed as a real number).

Mathematicians do not fret much about this ambiguity, because they know there are preferred injections

$$N \hookrightarrow Z \hookrightarrow Q \hookrightarrow R.$$

These injections are in fact *unique* with certain simple properties. For example, there is exactly one way to embed  $Q$  as a subfield of  $R$ .

Better still, each of these number systems satisfies a universal property:

- $N$  is the free commutative monoid on one generator;
- $Z$  is the group completion of  $N$ ;
- $Q$  is the field of fractions of  $Z$ ;
- $R$  is the Cauchy completion of  $Q$ .

Each of these universal properties characterizes maps from these objects in certain categories.

To *construct* these objects set-theoretically and to prove that they have the desired properties is sometimes a chore. There are often many constructions of the same object. For example, are real numbers Dedekind cuts, or are they equivalence classes of Cauchy sequences of rational numbers? If we ask questions that involve the *elements* of a real number, then we can observe differences between these two options. But if the kinds of questions we study only involve the things for which we usually use real numbers – adding, subtracting, multiplying, dividing, and taking limits – then any differences among the various constructions of  $R$  are unimportant.

Even further, working mathematicians don't generally regard the question 'is  $3 \in \pi$ ?' as *meaningful*, even though it technically will have an answer. It is precisely *because* the answer depends upon the set-theoretic model one chooses of the real numbers that we aren't supposed to ask that sort of question. That is, we adopt a *structuralist* attitude to the real numbers. Every complete ordered field has a unique element that deserves the name  $\pi$ , and what we call the *meaningful* questions about  $\pi$  make reference only to that structure. Since any pair of complete ordered fields are topologically isomorphic in exactly one way, the answers do not depend on any particular construction of the complete ordered field.

Note that we may still *answer* meaningful questions by appealing to a particular model. One may deduce facts about  $\pi$  by understanding it as an equivalence class of Cauchy sequences. But those facts are only meaningful (in our sense) if they can be stated only with reference to the structures present in a complete ordered field.

This pattern of mathematical development resembles Wittgenstein's parable. We climb a ladder by constructing a mathematical object  $X$  in a set-theoretical manner. Once we've done this, we identify the salient *structures* and *properties* of  $X$ . We write enough of these down to characterize  $X$  uniquely, up to an appropriate notion of *isomorphism*. The structures we specify will, perhaps, reveal to us a category  $C$  of which it should be viewed as an object, and the properties will identify it uniquely up to unique isomorphism in  $C$ . We then restrict our attention to the questions about  $X$  that can be formulated in terms provided by  $C$ ,

and we regard questions about  $X$  that do not admit such formulations as meaningless. Details about our initial construction of  $X$  become uninterrogable, and thus we throw away the ladder.

The theory of higher categories functions also follows this pattern, to a point. In fact, there are many ways to construct a theory of higher categories. These constructions vary significantly in detail. However, there are also today a number of different *unicity theorems*; these state that any two purported models of higher categories satisfying a handful of reasonable axioms are equivalent in an appropriate sense. In other words, all of these are models of the same structure. That structure is the *higher category of higher categories*. We will have more to say about this below.

Before we do, though, we must acknowledge that this does seem to introduce a little wrinkle in our story. After all,  $\mathbf{R}$  is not itself a real number; one can define complete ordered fields, without making reference to an existing theory of real numbers. But higher categories do form a higher category. Is it not paradoxical to assert that there is a unique higher category of higher categories? Are we not trying to throw away our ladder while we are still standing on it? After all, how can one characterize the theory of higher categories as a higher category before one has fully worked out what a higher category is? And how can one claim to have fully worked out what a higher category is without having characterized the theory of higher categories?

The strategy is to begin with a definition (in set-theoretic terms) of *putative* higher categories. We show that putative higher categories form a putative higher category  $\mathbf{Put}$ . Then we uniquely characterize an object  $\mathbf{True}$  of  $\mathbf{Put}$ , making reference only to the structure available in  $\mathbf{Put}$ . We call  $\mathbf{True}$  the putative higher category of *true* higher categories. Then we prove that  $\mathbf{Put}$  satisfies the conditions of our characterization. Hence the putative higher category  $\mathbf{Put}$  of putative higher categories is equivalent (in a unique fashion) to the putative higher category  $\mathbf{True}$  of true higher categories.

It is easy to tell a degenerate version of this story. I define a putative higher category to be a one-point set. The category  $\mathbf{Put}$  of one-point sets is, up to equivalence, a one-point set itself. We characterize  $\mathbf{True}$  as the unique object of  $\mathbf{Put}$  (up to unique isomorphism). Necessarily,  $\mathbf{Put} \cong \mathbf{True}$ . Obviously, we want a theory of higher categories with more content than this one.

We conclude that the theory of higher categories, as we can develop it today, differs from many other mathematical abstractions in one important respect. Whereas we are eventually able to find new (and often clearer) *definitions* of many mathematical objects by adopting structuralist attitudes, we do not have a way of constructing a theory of higher categories without introducing a model of the theory at some point. We can, for example, give a structuralist defini-

tion of 'real number' as an element of a complete ordered field  $\mathbf{R}$ ; such a definition doesn't exhibit any preference for any particular construction of  $\mathbf{R}$ . By contrast, we do not currently know how to give a completely structuralist definition of 'higher category'. What we have is a structuralist *characterization* of the theory of higher categories, when this theory is regarded as an object in some extant model of higher categories. So it appears that we cannot avoid the difficult task of constructing and studying an explicit model of higher categories. Such a model remains entangled with the theory of higher categories, even when the goal is a model-independent understanding of the theory.

What this means for us is that, if we are to undertake a well-motivated study of higher categories, then we will have to spend some time developing good intuitions about these objects.

### The landscape of higher categories

At first it's hard to see what all the fuss is about. We already know what 0-categories are: they're sets. We also know what 1-categories are: they're categories. So a 1-category has a collection of objects and, between every pair  $x, y$  of objects, one has a 0-category (=set)  $\text{Mor}(x, y)$  of maps. Composition is then a map

$$\text{Mor}(x, y) \times \text{Mor}(y, z) \rightarrow \text{Mor}(x, z)$$

given by  $(f, g) \mapsto g \circ f$ . The right way to iterate this definition seems uncontroversial.

Let  $V$  be a category with all finite products. A *category  $C$  enriched in  $V$*  consists of:

- a collection  $\text{Obj } C$  of objects;
- between every pair  $x, y \in \text{Obj } C$ , an object

$$\text{Mor}_C(x, y) \in \text{Obj } V ;$$

- for every  $x \in \text{Obj } C$ , a morphism  $\text{id}_x : 1_V \rightarrow \text{Mor}_C(x, x)$  (where  $1_V$  denotes the terminal object of  $V$ ); and
- for every  $x, y, z \in \text{Obj } C$ , a morphism

$$\text{Mor}_C(x, y) \times \text{Mor}_C(y, z) \rightarrow \text{Mor}_C(x, z) ,$$

written  $(f, g) \mapsto g \circ f$ .

These data are subject to the usual axioms: composition is associative  $((h \circ g) \circ$

$f = h \circ (g \circ f)$ ), and unital ( $f \circ \text{id}_x = \text{id}_y \circ f = f$ ). There's an attached notion of *enriched functor*, whose definition is predictable.

Now we can give an easy recursive definition. Our base case is the notion of *strict 0-categories* and the category  $\text{Cat}_0^{\text{str}} := \text{Set}$ . Then we define a *strict  $n$ -category* as a category enriched in  $\text{Cat}_{n-1}^{\text{str}}$ , and we define  $\text{Cat}_n^{\text{str}}$  as the category of  $\text{Cat}_{n-1}^{\text{str}}$ -enriched categories and  $\text{Cat}_{n-1}^{\text{str}}$ -enriched functors.

Thus a strict 2-category consists of a set  $\text{Obj } \mathbf{C}$  of objects; between every  $a, b \in \text{Obj } \mathbf{C}$ , a set  $\text{Mor}_{\mathbf{C}}(a, b)$  of morphisms  $a \rightarrow b$ ; and between every  $f, g \in \text{Mor}_{\mathbf{C}}(a, b)$ , a set  $\text{Mor}_{\text{Mor}_{\mathbf{C}}(a, b)}(f, g)$  of 2-morphisms  $f \rightarrow g$ . Morphisms and 2-morphisms each have composition laws, which are associative and unital. Since  $\text{Mor}_{\mathbf{C}}(a, b)$  is actually a category, the composition law  $\text{Mor}_{\mathbf{C}}(a, b) \times \text{Mor}_{\mathbf{C}}(b, c) \rightarrow \text{Mor}_{\mathbf{C}}(a, c)$  is a functor. In particular, if  $f, g: a \rightarrow b$  and  $u, v: b \rightarrow c$  are morphisms, and if  $\eta: f \rightarrow g$  and  $\theta: u \rightarrow v$  are 2-morphisms, then we have a *horizontal composition*  $\theta * \eta: u \circ f \rightarrow v \circ g$ . The horizontal composition is related to the vertical composition by means of an *interchange formula*:

$$(\nu * \mu) \circ (\theta * \eta) = (\nu \circ \theta) * (\mu \circ \eta).$$

Unwinding the recursion, we see that a strict  $n$ -category  $\mathbf{C}$  has:

- a collection  $\text{Obj } \mathbf{C}$  of *objects* or *0-morphisms*;
- for every pair  $a, b \in \text{Obj}(\mathbf{C})$  of objects, a collection  $\text{Mor}_{\mathbf{C}}(a, b)$  of *morphisms* or *1-morphisms* with *source*  $a$  and *target*  $b$ ;
- for every pair  $f, g \in \text{Mor}_{\mathbf{C}}(a, b)$  of 1-morphisms (which we say are *parallel* because they have the same source, and they have the same target), a collection  $\text{Mor}_{\text{Mor}_{\mathbf{C}}(a, b)}(f, g)$  of *2-morphisms* with source  $f$  and target  $g$ ;
- for every parallel pair  $\alpha, \beta \in \text{Mor}_{\text{Mor}_{\mathbf{C}}(a, b)}(f, g)$  of 2-morphisms, a collection

$$\text{Mor}_{\text{Mor}_{\text{Mor}_{\mathbf{C}}(a, b)}(f, g)}(\alpha, \beta)$$

of *3-morphisms* with source  $\alpha$  and target  $\beta$ ;

...

- for every parallel pair  $\phi, \psi$  of  $(n-1)$ -morphisms, a collection

$$\text{Mor}_{\text{Mor} \cdots \text{Mor}_{\mathbf{C}}(a, b) \cdots}(\phi, \psi)$$

$\text{Mor}(\phi, \psi)$  of  *$n$ -morphisms* with source  $\phi$  and target  $\psi$ .

Each of these kinds of morphisms can be composed

There is a theory of  $(n, k)$ -categories for  $0 \leq k \leq n \leq +\infty$ . When are two mathematical objects the same? Let's start with natural numbers  $a$  and  $b$ . Perhaps you want to prove that  $a$  and  $b$  are the same. How might you go about that? Well,

it depends upon how  $a$  and  $b$  arose in your thinking. Since they are natural numbers, it's likely you found them by counting something. In other words,  $a$  is the cardinality of a finite set  $A$ , and  $b$  is the cardinality of a finite set  $B$ .

Perhaps  $A$  is the set of nontrivial ways of (correctly and nonredundantly) parenthesizing an expression like  $abcd$  with two pairs of matching parentheses, such as  $(a(bc))d$ . Perhaps  $B$  is the set of full binary trees with 4 leaves. It would be perfectly valid to prove that  $a = b$  by computing each of these numbers and compare the answers, but one feels as though one has

At first it seems a little strange to speak about the category of categories. These kinds of constructions seem useful and interesting.

## QUASICATEGORIES: THE LADDER

# 1

## Grothendieck's homotopy hypothesis

The mission of homotopy theory is to iteratively enhance every *property* of a mathematical object to *structure* on it. The homotopy theorist deconstructs the equals sign by this process: they no longer regard ' $x = y$ ' as a property that  $x$  and  $y$  together possess, but rather as piece of structure that connects  $x$  and  $y$ . That structure is then a *path* between  $x$  and  $y$ . Semantically, we consider this path as a *reason* for – or as a *witness* to – the equality ' $x = y$ '.

If  $\alpha$  and  $\beta$  are paths connecting  $x$  and  $y$ , then again we do not wish to speak of ' $\alpha = \beta$ ' as a property, but as a further piece of structure – a *homotopy* between  $\alpha$  and  $\beta$ . We iterate: two homotopies are no longer merely 'equal', but they may be connected by *higher homotopies*; two higher homotopies may be connected by further higher homotopies, *etc., etc., ad infinitum*.

The data of all these points and paths and homotopies and higher homotopies, taken together, constitute an *anima* (plural: *animae*). Animae are also called *spaces*, *homotopy types*, *Kan complexes*, or  $\infty$ -*groupoids*. These terms each reflect a certain attitude toward these objects. The terms 'space' and 'homotopy type' acknowledge that these objects were first modelled and understood using topological spaces and topological notions of homotopy. A 'Kan complex' is then a combinatorial blueprint for these homotopies and their relations. The phrase ' $\infty$ -groupoid' then reinterprets the (higher) homotopies as (higher) *symmetries*. The fact that these terms can all be used interchangeably is a nontrivial insight – Grothendieck's *homotopy hypothesis*. We will formulate and prove a version of this sentence in this chapter – surely not the version Grothendieck had in mind, but one that is better-adapted to the needs of contemporary mathematicians. In our formulation, it becomes a theorem of Kan.

Our adoption of 'anima' reflects our desire not to favor any one of these attitudes. Animae are for us fundamental objects: they play the same role in *homotopical mathematics* that sets play in 'ordinary' mathematics. In ordinary set-

theoretic mathematics, every object is ultimately defined in terms of sets; similarly, every object in homotopical mathematics is defined in terms of animae.

Symmetries of objects were certainly central to the mathematics of the 19th century, but it's a distinctly 20th century concept that symmetries might meaningfully have their own symmetries. (It is interesting to consider the origins of this idea, but it would be difficult to pinpoint the first person who seriously considered it.) In any case, the 20th century provided three realizations about homotopy theory's iterative enhancement process.

- 1 Foremost was the promise of interesting new phenomena to study. Homological algebra appears at first to be a relatively featureless outgrowth of linear algebra. The Bockstein homomorphism is an early illustration that ordinary modules interact in new ways in derived settings. But it's the nontriviality of the Hopf element  $\eta$  in the stable homotopy group  $\pi_1^s$  that decisively separates *homological algebra* – ordinary algebra that is then derived – from *homotopical algebra* – algebra done in a natively homotopical setting. The first signal from the mysterious world of homotopical algebra was a short message: ' $\eta \neq 0$ '.
- 2 In spite of our informal description of homotopy theory as an inductive enhancement of properties into structure, by the middle of the 20th century, the idea had been made precise, and it had become part of the standard toolkit of algebraic topology.

In fact, it can now be made precise in a number of different ways. On one hand, we can model homotopical structures entirely via ordinary mathematical objects. We could, for example, model them using topological structures. For reasons we discuss below, we will adopt the Kanian approach and encode homotopical structures using *simplicial diagrams*.

Alternatively – and in a spirit closer to that of this introduction – one might instead attempt to rewrite the logical foundations of mathematics in a way that bakes in our preference for structure over properties. This is the approach of *homotopy type theory*, a stirring vision of new foundations in mathematics. As of this writing, homotopy type theory is still in its infancy. In later editions of this book, perhaps the combinatorics of simplices will be replaced by fundamental facts about type theory.

- 3 Once it was understood how to model homotopical structures accurately, new questions arose: *how do we construct models that are maximally useful? what does it mean to say that two models represent the same homotopy theory? shouldn't this notion of sameness, whatever it is, be subject to the same inductive refinement process that got us here?* These questions lay at the heart of the many foundational developments in homotopy theory starting in the 1970s.

By the end of the millennium it was clear that one would need to take a further step, and contemplate a *homotopy theory of homotopy theories*. Just as Grothendieck had seen that ordinary homotopy theory should be equivalent to the theory of  $\infty$ -groupoids, Joyal, Kan, Rezk, Simpson, and Toen all recognized that the homotopy theory of homotopy theories should be equivalent to the theory of  $\infty$ -categories.

Our approach to constructing the homotopy theory of animae follows a general recipe, which will inform our work throughout this book. The recipe provides a strategy for designing a homotopy theory  $E$ , using only partial or imperfect information about it:

- 1 Select a piece  $E_0$  of  $E$  that is simple enough that you can understand it completely, but complex enough so that any object  $X \in E$  is completely determined by the sets/groups/whatevers of maps  $T \rightarrow X$  with  $T \in E_0$ . In many cases, you'll want  $E_0$  to generate  $E$  under suitable colimits.
- 2 Now select a small category  $J$ , usually combinatorial in nature, along with an essentially surjective functor  $R: J \rightarrow E_0$  (which need not be fully faithful). In many cases, it will be helpful if the objects of  $J$  come equipped with some notion of *degree*. The category  $J$  and functor  $R$  should be chosen so that some key salient features of general objects  $X \in E$  can be read off from mapping objects  $\text{Map}(R(j), X)$ .
- 3 Encode these salient features as a set of properties  $P$  of the corresponding functors  $\text{Map}(R(-), X)$ . For example, perhaps you'll want to require that for some particular  $j \in J$ , the object  $\text{Map}(R(j), X)$  is trivial. Or perhaps such a property expresses  $\text{Map}(R(k), X)$  as a limit or colimit of various other mapping objects  $\text{Map}(R(j), X)$ . The objects of your homotopy theory will be exactly the functors  $J^{op} \rightarrow \mathbf{Set}$  (or other enriching category) that enjoy these properties of  $P$ .

In this chapter, we will construct the homotopy theory of animae in this way:  $E_0$  will be the homotopy theory of contractible animae (which is trivial),  $J$  is the category of *simplices*  $\Delta$  (defined below), and  $P$  is Kan's *horn-filling condition*.

Other options for  $J$  (and therefore  $P$ ) are possible: there is an interesting class of categories – the *test categories* – that can stand in for  $\Delta$ . These include the category of nonempty finite sets, Joyal's categories  $\Theta_n$ , as well as various categories of cubes and trees.

One special feature of  $\Delta$  is that it can also be used to define the larger homotopy theory of  $\infty$ -categories itself. For this homotopy theory,  $E_0$  is the homotopy theory of finite ordinals (which is not trivial, but is nevertheless very

simple),  $J$  is again the category  $\Delta$ , and  $P$  is the *inner horn-filling condition* first identified explicitly by Boardman–Vogt.

### 1.1 Simplicial objects

Our aim is to convert equality from a property into a structure. At a minimum, we want to be able to work with notions of equivalence that are not just set-theoretic equality. Traditionally, such an alternative is described as an *equivalence relation* on a set  $S$ .

A *relation* is encoded by a subset  $R \subseteq S \times S$ , which is the subset of related pairs of elements. An *equivalence relation* is one that is reflexive, symmetric, and transitive:

- 1 Reflexivity is the condition that  $R$  contains the image of the *diagonal map*  $S \rightarrow S \times S$  given by  $x \mapsto (x, x)$ .
- 2 Symmetry is the condition that  $R$  is stable under the involution of  $S \times S$  given by  $(x, y) \mapsto (y, x)$ .
- 3 Transitivity states that the projection  $S \times S \times S \rightarrow S \times S$  given by  $(x, y, z) \mapsto (x, z)$  carries the subset  $R \times_S R \subseteq S \times S \times S$  to the subset  $R$ .

An equivalence relation on  $S$  can thus be converted into a diagram

$$R \times_S R \begin{matrix} \xrightarrow{\quad} \\ \xleftarrow{\quad} \end{matrix} R \begin{matrix} \xrightarrow{\quad} \\ \xleftarrow{\quad} \end{matrix} S, \quad (1.1.0.1)$$

The maps from left to right are various projections. The maps from right to left are various diagonal maps. The colimit of this diagram agrees with the coequalizer of the subdiagram

$$R \rightrightarrows S,$$

which is in turn the set of equivalence classes  $S/R$ .

The case we want to make is that this diagram shape is the start of a more natural *simplicial diagram*, extending infinitely off to the left:

$$\cdots \begin{matrix} \xrightarrow{\quad} \\ \xleftarrow{\quad} \end{matrix} R_2 \begin{matrix} \xrightarrow{\quad} \\ \xleftarrow{\quad} \end{matrix} R_1 \begin{matrix} \xrightarrow{\quad} \\ \xleftarrow{\quad} \end{matrix} R_0 .$$

This diagram can encode the higher forms of equivalence we sought in the introduction to this chapter.

Our diagram (1.1.0.1) does not capture the symmetry property of  $R$ . It would be a simple matter to incorporate actions of the symmetric groups  $\Sigma_2$  and  $\Sigma_3$  on  $R$  and  $R \times_S R$  into our diagram. This would lead us to the theory of *symmetric simplicial sets*. We will see in our story that the symmetry is encoded not in the

shape of a simplicial diagram of sets, but in the properties we demand of it when it models an anima. This asymmetry is as much a feature as it is a bug, however: it will be necessary when we want to connect the theory of simplicial sets to that of categories.

Nothing in the diagram (1.1.0.1) forces  $R$  to be a subset of  $S \times S$ ; we may demand only that  $R$  map to  $S \times S$ . The effect of this is to permit the elements of  $S$  to be equivalent in many ways. For example, if  $x, y \in S$ , then the fiber of the map  $R \rightarrow S \times S$  is a set

$$\ulcorner xRy \urcorner,$$

which is the set of ways in which  $x$  and  $y$  are equivalent – or witnesses to their equivalence. The middle map from  $R \times_S R \rightarrow R$  now carries two such witnesses,  $\beta \in \ulcorner xRy \urcorner$  and  $\gamma \in \ulcorner yRz \urcorner$ , to a composite witness  $\gamma\beta \in \ulcorner xRz \urcorner$ . But now we encounter a kind of *higher transitivity*: if  $\alpha \in \ulcorner wRx \urcorner$ , then there ought to be only one composite witness  $\gamma\beta\alpha \in \ulcorner wRz \urcorner$ . In other words, this composition should be *associative*:  $(\gamma\beta)\alpha = \gamma(\beta\alpha)$ . If it is, then what we have is the data of a *groupoid* whose objects are the elements of  $S$  and whose (iso)morphisms are elements of  $R$ , so that  $\text{Isom}(x, y) = \ulcorner xRy \urcorner$ .

The associativity also lets us extend our diagram (1.1.0.1) to a larger diagram

$$R \times_S R \times_S R \begin{array}{c} \rightrightarrows \\ \rightleftarrows \\ \rightleftarrows \end{array} R \times_S R \begin{array}{c} \rightrightarrows \\ \rightleftarrows \end{array} R \rightleftarrows S. \quad (1.1.0.2)$$

These diagrams are now becoming sufficiently complicated that we need to be more pedantic about the indexing categories we're using.

### 1.1.1 The simplex category

**Definition 1.1.1.1** The *simplex category*  $\Delta$  is the category whose objects are nonempty, totally ordered, finite sets, and whose morphisms the monotonic maps between these.

Every object of  $\Delta$  is uniquely isomorphic to a finite ordinal

$$[n] = \{0 < 1 < \dots < n\}$$

for some integer  $n \geq 0$ . This entitles us to refer to objects of  $\Delta$  as if they are all of this form.

Between these, we have the following morphisms:

- for every  $j \in [n]$ , the *face map* is the injective map  $\delta_j: [n-1] \rightarrow [n]$  whose image does not contain  $j$ ;

- for every  $i \in [n]$ , the *degeneracy map* is the surjective map  $\sigma_i: [n+1] \rightarrow [n]$  that carries  $i+1$  to  $i$ .

Every other map in the simplex category can be expressed as a composite of face and degeneracy maps. It is elementary (but boring) to prove that  $\Delta$  is generated by these face and degeneracy maps, subject only to the following relations, called the *simplicial identities*:

- if  $i \leq j$ , then

$$\delta_i \delta_j = \delta_{j+1} \delta_i ;$$

- if  $i \leq j$ , then

$$\sigma_j \sigma_i = \sigma_i \sigma_{j+1} ;$$

- for every  $i, j$ ,

$$\sigma_j \delta_i = \begin{cases} \delta_i \sigma_{j-1} & \text{if } i < j ; \\ \text{id} & \text{if } i \in \{j, j+1\} ; \\ \delta_{i-1} \sigma_j & \text{if } j+1 < i . \end{cases}$$

In practice, the generators-and-relations description of  $\Delta$  is usually more trouble than it's worth, but it does provide a schematic picture of the category  $\Delta$ :

$$[0] \begin{array}{c} \rightrightarrows \\ \leftarrow \\ \rightleftarrows \end{array} [1] \begin{array}{c} \rightrightarrows \\ \leftarrow \\ \rightleftarrows \end{array} [2] \begin{array}{c} \rightrightarrows \\ \leftarrow \\ \rightleftarrows \end{array} [3] \begin{array}{c} \rightrightarrows \\ \leftarrow \\ \rightleftarrows \end{array} \cdots ,$$

as well as its opposite  $\Delta^{op}$ :

$$\cdots \begin{array}{c} \rightrightarrows \\ \leftarrow \\ \rightleftarrows \end{array} [3] \begin{array}{c} \rightrightarrows \\ \leftarrow \\ \rightleftarrows \end{array} [2] \begin{array}{c} \rightrightarrows \\ \leftarrow \\ \rightleftarrows \end{array} [1] \begin{array}{c} \rightrightarrows \\ \leftarrow \\ \rightleftarrows \end{array} [0]$$

**Notation 1.1.1.2** For any integer  $n \geq 0$ , we define  $\Delta_{\leq n} \subset \Delta$  as the full subcategory spanned by the objects  $[k]$  with  $k \leq n$ .

We started by contemplating an equivalence relation  $R$  on  $S$  in a diagrammatic way. That gave us diagram (1.1.0.1), which we now can describe efficiently as a functor  $X: \Delta_{\leq 2}^{op} \rightarrow \mathbf{Set}$  that carries  $[0]$  to  $S$ ,  $[1]$  to  $R$ , and  $[2]$  to  $R \times_S R$ .

Our job is to replace properties with structure, so we then considered what happens if you allow the possibility of different ways of being equivalent. The equivalence relation becomes a groupoid;  $S$  becomes the set of objects;  $R$  becomes the set of morphisms. The transitivity condition becomes a composition structure. That new structure was encoded in a map  $R \times_S R \rightarrow R$ , and we asked it to satisfy a *coherence condition*, which asserted the associativity of composition.

That associativity is then expressed in the larger diagram (1.1.0.2), which is a functor  $\Delta_{\leq 3}^{op} \rightarrow \mathbf{Set}$  that carries [3] to  $R \times_S R \times_S R$ .

But let's examine the meaning of associativity in our groupoid a little more carefully. The value of associative laws is that they permit us to make sense of composites not only of pairs of morphisms

$$x \rightarrow y \rightarrow z ,$$

but also of triples of morphisms

$$w \rightarrow x \rightarrow y \rightarrow z ,$$

and even of arbitrary finite sequences of morphisms

$$x_0 \rightarrow x_1 \rightarrow \cdots \rightarrow x_n .$$

That's a subtle shift of perspective here that we want to take a moment to appreciate. We were never *really* interested in the equation  $(\gamma\beta)\alpha = \gamma(\beta\alpha)$ ; what we wanted was to say that there was an unambiguous meaning to the expression  $\gamma\beta\alpha$  and even of  $\alpha_n\alpha_{n-1}\cdots\alpha_1$ .

In other words, the data in which we are ultimately interested is not that of a single multiplication law  $R \times_S R \rightarrow R$ , but in fact of a family of multiplication laws

$$R^{\times_S n} := R \times_S R \times_S \cdots \times_S R \rightarrow R ,$$

one for each  $n$ . Associativity is then the expression of the compatibility between these. This is all packaged up very neatly in the functor  $\Delta^{op} \rightarrow \mathbf{Set}$  that carries  $[n]$  to  $R^{\times_S n}$ . This is our first example of a *simplicial object*.

### 1.1.2 Simplicial & cosimplicial

**Definition 1.1.2.1** Let  $C$  be a category. A *simplicial object* of  $C$  is a functor  $\Delta^{op} \rightarrow C$ . A *cosimplicial object* of  $C$  is a functor  $\Delta \rightarrow C$ . We write

$$sC := \text{Fun}(\Delta^{op}, C) \quad \text{and} \quad cC := \text{Fun}(\Delta, C) .$$

If  $X \in sC$ , then we write  $X_n$  for the value  $X([n])$ , and if  $Y \in cC$ , then we write  $Y^n$  for the value  $Y([n])$ . At times it may be convenient to write  $X_\bullet$  and  $Y^\bullet$  instead of  $X$  and  $Y$ , just to emphasize the variance.

Thus a simplicial object  $X_\bullet$  specifies object  $X_0, X_1, \dots$ , along with *face maps*  $d_j: X_n \rightarrow X_{n-1}$  for each  $j \in [n]$  and *degeneracy maps*  $s_i: X_n \rightarrow X_{n+1}$  for each  $i \in [n]$ :

$$\cdots \begin{array}{c} \rightrightarrows \\ \rightrightarrows \\ \rightrightarrows \end{array} X_3 \begin{array}{c} \rightrightarrows \\ \rightrightarrows \\ \rightrightarrows \end{array} X_2 \begin{array}{c} \rightrightarrows \\ \rightrightarrows \\ \rightrightarrows \end{array} X_1 \begin{array}{c} \rightrightarrows \\ \rightrightarrows \\ \rightrightarrows \end{array} X_0 .$$

We will be interested in simplicial objects of a number of different categories, but our big interest is the theory of simplicial sets.

**Example 1.1.2.2** If  $[m], [n] \in \Delta$ , then let us write

$$\Delta_m^n := \text{Mor}_\Delta([m], [n]) .$$

Thus for each  $[n] \in \Delta$ , we have the simplicial set it represents

$$\Delta^n := \text{Mor}_\Delta(-, [n]) : \Delta^{op} \rightarrow \mathbf{Set} .$$

We call  $\Delta^n$  the *standard  $n$ -simplex*. The assignment  $[n] \mapsto \Delta^n$  is a functor  $\Delta \rightarrow \mathbf{sSet}$ . Equally, for each  $[m] \in \Delta$ , we have the cosimplicial set it corepresents

$$\Delta_m := \text{Mor}_\Delta([m], -) : \Delta \rightarrow \mathbf{Set} ,$$

and the assignment  $[m] \mapsto \Delta_m$  is a functor  $\Delta^{op} \rightarrow \mathbf{cSet}$ .

The standard simplices play a critical role in the theory of simplicial sets. The Yoneda lemma implies that for every simplicial set  $X$ , we have a natural isomorphism

$$X_n = \text{Mor}_{\mathbf{sSet}}(\Delta^n, X) .$$

An element  $\sigma \in X_n$  – or equivalently a map  $\sigma : \Delta^n \rightarrow X$  – is called an  *$n$ -simplex of  $X$* . If  $n = 0$ , we may call this a *vertex*; if  $n = 1$ , we may call this an *edge*.

Every simplicial set  $X \in \mathbf{sSet}$  is the colimit of its simplices. More precisely, consider the Yoneda embedding  $\Delta \rightarrow \mathbf{sSet}$  given by  $[n] \mapsto \Delta^n$ , and let

$$\Delta_{/X} := \Delta \times_{\mathbf{sSet}} \mathbf{sSet}_{/X} .$$

We call  $\Delta_{/X}$  the *category of simplices of  $X$* . We now have a canonical isomorphism

$$\text{colim}_{[n] \in \Delta_{/X}} \Delta^n = X .$$

Said differently, the left Kan extension of the Yoneda embedding  $\Delta \rightarrow \mathbf{sSet}$  is the identity functor on  $\mathbf{sSet}$ . We will discuss this much more carefully in 1.1.3.

**Example 1.1.2.3** Let  $A$  be a small category. The *nerve*  $N_\bullet A$  is the simplicial set that carries  $[n]$  to the set of functors  $[n] \rightarrow A$ .

In other words, by regarding each nonempty totally ordered finite set  $[n]$  as a category, we obtain a fully faithful inclusion  $\Delta \hookrightarrow \mathbf{Cat}$ . The nerve  $N_\bullet A$  is the composite of  $\Delta^{op} \hookrightarrow \mathbf{Cat}^{op}$  with the functor  $\mathbf{Cat}^{op} \rightarrow \mathbf{Set}$  represented by  $A$ .

Thus  $N_0 A$  is the set of objects of  $A$ , and  $N_1 A$  is the set of morphisms. If  $f : x \rightarrow y$  is a morphism of  $A$ , then  $d_0(f) = y$ , and  $d_1(f) = x$ . For any object  $x$  of  $A$ , the degenerate 1-simplex  $s_0(x)$  is the identity at  $x$ .

The set  $N_2 A$  of 2-simplices is the set of commutative triangles

$$\begin{array}{ccc} & y & \\ f \nearrow & & \searrow g \\ x & \xrightarrow{h} & z \end{array}$$

in  $A$ . If we call this 2-simplex  $\alpha$ , then  $d_0(\alpha) = g$ ,  $d_1(\alpha) = h$ , and  $d_2(\alpha) = f$ . For every morphism  $f: x \rightarrow y$  of  $A$ , we also have two degenerate 2-simplices  $s_0(f)$  and  $s_1(f)$ , which correspond to the commutative triangles

$$\begin{array}{ccc} & x & \\ \text{id} \nearrow & & \searrow f \\ x & \xrightarrow{f} & y \end{array} \quad \text{and} \quad \begin{array}{ccc} & y & \\ f \nearrow & & \searrow \text{id} \\ x & \xrightarrow{f} & y \end{array},$$

respectively.

If  $S$  is the set of objects of  $A$  and  $R$  is its set of morphisms, then we find that  $N_n A$  is the  $n$ -fold fiber product  $R^{\times_s n}$ . The simplicial objects we extracted from relations and groupoids are therefore examples of nerves.

In particular, the standard  $n$ -simplex  $\Delta^n$  is precisely the nerve  $N_\bullet[n]$ .

**Proposition 1.1.2.4** *The nerve functor  $N_\bullet: \mathbf{Cat} \rightarrow \mathbf{sSet}$  is fully faithful.*

*Proof* Let  $C$  and  $D$  be categories, and let  $f: N_\bullet C \rightarrow N_\bullet D$  be a morphism of simplicial sets. We aim to show that there exists a unique functor  $F: C \rightarrow D$  such that  $f = N_\bullet F$ .

If  $F: C \rightarrow D$  is a functor such that  $N_\bullet F = f$ , then on objects,  $F$  is the map  $f_0: N_0 C \rightarrow N_0 D$ , and on morphisms,  $F$  is the map  $f_1: N_1 C \rightarrow N_1 D$ . So our  $F$  is certainly unique if it exists.

So define  $F$  accordingly: on objects, take the map  $f_0$ , and on morphisms, take the map  $f_1$ . The compatibility of  $f$  with the face map  $d_1: N_2 \rightarrow N_1$  shows that  $F$  respects composition. The compatibility of  $f$  with the degeneracy map  $s_0: N_0 \rightarrow N_1$  shows that  $F$  respects identities. Hence  $F$  is indeed a functor.  $\square$

This proposition guarantees that we lose no information when we pass from categories to simplicial sets.

### 1.1.3 Interlude: generators & relations of categories

We mentioned above (??) that every simplicial set is the colimit of its simplices. In other words, every simplicial set is well approximated by simplices.

More generally, let  $\mathbf{C}$  be a category with all small colimits. In most cases,  $\mathbf{C}$

will be a large category.<sup>1</sup> We are interested in situations in which, even though  $\mathbf{C}$  is large, all of its objects are well approximated – or even *determined* – by a small subcategory  $A \subseteq \mathbf{C}$  via colimits. This will be an idea that plays a big role in our work, so let's discuss it carefully.

**Definition 1.1.3.1** Let  $\mathbf{C}$  be a category with all colimits, and let  $A \subseteq \mathbf{C}$  be a small full subcategory. We say that  $A$  *generates  $\mathbf{C}$  under colimits* if the smallest full subcategory  $\mathbf{D} \subseteq \mathbf{C}$  that is closed under colimits and contains  $A$  is  $\mathbf{C}$  itself.

We say that  $A$  *strongly generates  $\mathbf{C}$  under colimits* – or that  $A$  is *dense* in  $\mathbf{C}$  – if the left Kan extension of the inclusion  $A \subseteq \mathbf{C}$  along itself is the identity functor on  $\mathbf{C}$ .

For every object  $X \in \mathbf{C}$ , we have the category

$$A_{/X} := A \times_{\mathbf{C}} \mathbf{C}_{/X} ,$$

whose objects are pairs  $(a, f)$  consisting of an object  $a \in A$  and a morphism  $f: a \rightarrow X$  in  $\mathbf{C}$ . The left Kan extension of the inclusion  $A \hookrightarrow \mathbf{C}$  along itself is the functor that carries an object  $X \in \mathbf{C}$  to the colimit  $\operatorname{colim}_{a \in A_{/X}} a$ . Thus  $A$  is dense in  $\mathbf{C}$  if and only if, for every object  $X \in \mathbf{C}$ , the natural morphism

$$\operatorname{colim}_{a \in A_{/X}} a \rightarrow X$$

is an isomorphism. So if  $A$  strongly generates  $\mathbf{C}$ , then every object of  $\mathbf{C}$  is a colimit of objects in  $A$  in a canonical way. So certainly if  $A$  is dense in  $\mathbf{C}$ , then it generates  $\mathbf{C}$  under colimits, but the converse is far from true. In fact, if  $A$  generates  $\mathbf{C}$  under colimits, then it need not even be the case that every object of  $\mathbf{C}$  can be written as a colimit of objects from  $A$ .

**Example 1.1.3.2** Consider the full subcategory  $\{*\} \subset \mathbf{Set}$  generated by the one-point set. The category  $\{*\}$  is dense in  $\mathbf{Set}$ . To see this, let  $S$  be a set, and consider the category  $\{*\}_{/S}$ . An object of  $\{*\}_{/S}$  is nothing more than an element of  $S$ , and there are no non-identity morphisms in  $\{*\}_{/S}$  (because there are none in  $\{*\}$ !). Hence  $\{*\}_{/S}$  is the set  $S$ , viewed as a category. Thus

$$\operatorname{colim}_{s \in \{*\}_{/S}} s = \coprod_{s \in S} \{s\} = S .$$

**Example 1.1.3.3** Let's generalize this example. Let  $A$  be a small category, and

<sup>1</sup> In fact, a small category  $\mathbf{C}$  with all small coproducts is automatically a *preorder*. That is, if  $x, y \in \mathbf{C}$  are two objects, then we claim that there is at most one map  $x \rightarrow y$ . To prove this, suppose that  $\kappa$  is the cardinality of the set of morphisms of  $\mathbf{C}$ , and consider the coproduct  $\kappa \cdot x = \coprod_{\alpha < \kappa} x$ . Now  $\mathbf{C}(\kappa \cdot x, y) = \mathbf{C}(x, y)^\kappa$ , so by Cantor, if  $\#\mathbf{C}(x, y) \geq 2$ , then  $\#\mathbf{C}(\kappa \cdot x, y) \geq 2^\kappa > \kappa$ , which contradicts our assumption.

let  $\mathbf{P}(A)$  be the category of *presheaves* on  $A$  – i.e., functors  $A^{op} \rightarrow \mathbf{Set}$ . Thus

$$\mathbf{P}(A) = \mathbf{Fun}(A^{op}, \mathbf{Set}),$$

and in particular  $s\mathbf{Set} = \mathbf{P}(\Delta)$ . Now via the Yoneda embedding  $\mathcal{Y}: A \hookrightarrow \mathbf{P}(A)$ , we consider  $A$  as a full subcategory of  $\mathbf{P}(A)$ .

The category  $A$  is dense in  $\mathbf{P}(A)$ . To prove this, consider a presheaf  $F: A^{op} \rightarrow \mathbf{Set}$ . An object of the category  $A_{/F}$  is a pair  $(a, f)$  consisting of an object  $a \in A$  and a natural transformation  $f: \mathcal{Y}_a \rightarrow F$ . By Yoneda, such a natural transformation is the same thing as an element  $f \in F(a)$ . Thus  $A_{/F}$  is sometimes called the *category of elements of  $F$* . To prove that the canonical natural transformation

$$\eta: \operatorname{colim}_{a \in A_{/F}} \mathcal{Y}_a \rightarrow F$$

is an isomorphism, let  $b \in A$  be an object, and consider the map

$$\eta_b: \operatorname{colim}_{a \in A_{/F}} \operatorname{Mor}_A(b, a) \rightarrow F(b).$$

The elements of the colimit on the left are equivalence classes of triples  $(a, f, \phi)$  consisting of an object  $a \in A$ , an element  $f \in F(a)$ , and a morphism  $\phi: b \rightarrow a$  in  $A$ . The equivalence relation is generated by the demand that if  $(a, f, \phi)$  and  $(a', f', \phi')$  are such triples, and if there exists a map  $\gamma: a \rightarrow a'$  such that  $\phi' = \gamma\phi$  and  $F(\gamma)(f') = f$ , then  $(a, f, \phi)$  and  $(a', f', \phi')$  are equivalent. The map  $\eta_b$  carries such a triple to  $F(\phi)(f) \in F(b)$ . The aim is to show that this map is a bijection.

So let  $g \in F(b)$ . Then  $(b, g) \in A_{/F}$  is an object, and  $\operatorname{id}_b \in A(b, b)$  provides an element  $(b, g, \operatorname{id}_b)$  of the colimit on the left, and  $\eta_b(b, g, \operatorname{id}_b) = g$ . Furthermore, if  $(a, f, \phi)$  is an element of the colimit such that  $F(\phi)(f) = \eta_b(a, f, \phi) = g$ , then by definition,  $\phi: b \rightarrow a$  is a morphism such that  $\phi = \phi \operatorname{id}_b$  and  $F(\phi)(f) = g$ ; thus  $(a, f, \phi)$  is equivalent to  $(b, g, \operatorname{id}_b)$ .

**Example 1.1.3.4** Let  $\mathbf{Ab}$  denote the category of abelian groups, and let  $F \subset \mathbf{Ab}$  be the full subcategory spanned by the single object  $\mathbf{Z}$ . (In other words,  $F$  is the category of free abelian groups of rank 1.) What kinds of colimits can we form from  $F$ ?

Certainly any free abelian group is a colimit of objects of  $F$ , since we can form the coproducts

$$\mathbf{Z}\{S\} := \bigoplus_{s \in S} \mathbf{Z}$$

for every set  $S$ . Now if  $E$  is any abelian group, then we claim that we can write  $E$  as a colimit of free abelian groups.

There's really only one way to prove that an object can be written as a colimit

of some ‘nice’ objects: we have to somehow cook up a good supply of maps from the nice objects to our object. In our case, we can get away with a single map, as long as it is an epimorphism. We select a set  $S \subseteq E$  of generators for  $E$ . (If we’re feeling lazy or wasteful, we can choose  $S = E$ .) This defines an epimorphism

$$\phi: \mathbf{Z}\{S\} \rightarrow E.$$

Now the kernel of  $\phi$  is a subgroup  $K \subseteq \mathbf{Z}\{S\}$  such that  $E = \mathbf{Z}\{S\}/K$ . It turns out that  $K$  itself is automatically free, but that isn’t obvious, and in any case we don’t really need that fact. All we need to do is select some generators  $T \subseteq K$ . Now we have a homomorphism  $\mathbf{Z}\{T\} \rightarrow \mathbf{Z}\{S\}$  whose image is  $K$ , so that  $E$  is a pushout:

$$\begin{array}{ccc} \mathbf{Z}\{T\} & \longrightarrow & \mathbf{Z}\{S\} \\ \downarrow & & \downarrow \\ 0 & \longrightarrow & E \end{array}$$

We have thus shown that every abelian group can be written as a colimit of free groups, and that every free group can be written as a colimit of copies of  $\mathbf{Z}$ . This implies that our subcategory  $F$  generates  $\mathbf{Ab}$  under colimits.

But  $F_1$  does not *strongly* generate  $\mathbf{Z}$ . To see why not, let’s consider the category  $F_{/E}$  for an abelian group  $E$ . An object of  $F_{/E}$  is a homomorphism  $a: \mathbf{Z} \rightarrow E$ ; such a homomorphism is determined uniquely by the value  $a(1)$ , so we may regard the objects of  $F_{/E}$  as *elements* of  $E$ . In this way, if  $a, b \in E$  are two such objects, then a morphism  $m: a \rightarrow b$  is an integer  $m$  such that  $mb = a$  in  $E$ .

Suppose that  $\mathbf{C}$  is a category with colimits, and let us suppose that we want to write down a functor  $s\mathbf{Set} \rightarrow \mathbf{C}$  that preserves colimits.

#### 1.1.4 Skeletal & coskeletal

The simplicial objects we have been discussing so far have all been extended from the finite subcategories  $\Delta_{\leq n}$ . Let’s understand the mechanism for these extensions.

We write

$$s_{\leq n}C := \text{Fun}(\Delta_{\leq n}^{op}, C) \quad \text{and} \quad c^{\leq n}C := \text{Fun}(\Delta_{\leq n}, C).$$

Now restriction along the inclusion  $\Delta_{\leq n} \subset \Delta$  defines functors

$$sC \rightarrow s_{\leq n}C \quad \text{and} \quad cC \rightarrow c^{\leq n}C,$$

which we will denote by  $X \mapsto X_{\leq n}$  and  $Y \mapsto Y^{\leq n}$ .

**Definition 1.1.4.1** If  $C$  has finite colimits, then these functors each admit a fully faithful left adjoint given by left Kan extension:

$$\mathrm{sk}_n : s_{\leq n}C \hookrightarrow sC \quad \text{and} \quad \mathrm{sk}_n : c^{\leq n}C \hookrightarrow cC .$$

These are called the  $n$ -skeleton functors.

Dually, if  $C$  has finite limits, then these functors each admit a fully faithful right adjoint given by right Kan extension:

$$\mathrm{ck}_n : s_{\leq n}C \hookrightarrow sC \quad \text{and} \quad \mathrm{ck}_n : c^{\leq n}C \hookrightarrow cC .$$

These are called the  $n$ -coskeleton functors.

We have the usual formulas for these Kan extensions: if  $X \in s_{\leq n}C$ , then

$$\mathrm{sk}_n(X)_m = \operatorname{colim}_{[k] \in (\Delta_{\leq n})_{[m]}/}^{\operatorname{op}} X_k \quad \text{and} \quad \mathrm{ck}_n(X)_m = \lim_{[k] \in (\Delta_{\leq n})_{[m]}/}^{\operatorname{op}} X_k ,$$

and if  $Y \in c^{\leq n}C$ , then

$$\mathrm{sk}_n(Y)^m = \operatorname{colim}_{[k] \in \Delta_{\leq n}/[m]} Y^k \quad \text{and} \quad \mathrm{ck}_n(Y)^m = \lim_{[k] \in \Delta_{\leq n}/[m]} Y^k .$$

In the language of coends and ends:

$$\begin{aligned} \mathrm{sk}_n(X)_m &= \int^{[k] \in \Delta_{\leq n}} \Delta_m^k \times X_k \quad \text{and} \quad \mathrm{ck}_n(X)_m = \int_{[k] \in \Delta_{\leq n}} X_k^{\Delta_m^k} , \\ \mathrm{sk}_n(Y)^m &= \int^{[k] \in \Delta_{\leq n}} \Delta_m^k \times Y^k \quad \text{and} \quad \mathrm{ck}_n(Y)^m = \int_{[k] \in \Delta_{\leq n}} (Y^k)^{\Delta_m^k} . \end{aligned}$$

We will sometimes abuse notation slightly by writing  $\mathrm{sk}_n(X) = \mathrm{sk}_n(X_{\leq n})$  and  $\mathrm{ck}_n(X) = \mathrm{ck}_n(X_{\leq n})$  for a simplicial object  $X$ . That is, we will often regard the functors  $\mathrm{sk}_n$  and  $\mathrm{ck}_n$  as implicitly precomposed with the restriction  $sC \rightarrow s_{\leq n}C$ . The formulas above remain valid.

If  $C$  has all finite limits and colimits, and if  $X, Y \in sC$ , then we have natural bijections

$$\operatorname{Mor}_{sC}(\mathrm{sk}_n(X), Y) = \operatorname{Mor}_{s_{\leq n}C}(X_{\leq n}, Y_{\leq n}) = \operatorname{Mor}_{sC}(X, \mathrm{ck}_n(Y)) .$$

**Definition 1.1.4.2** Let  $C$  be a category with all finite limits and colimits, and let  $n \geq 0$  be an integer. A simplicial object  $X \in sC$  is  $n$ -skeletal if and only if the natural map  $\mathrm{sk}_n(X) \rightarrow X$  is an isomorphism. Accordingly,  $X$  is  $n$ -coskeletal if and only if the natural map  $X \rightarrow \mathrm{ck}_n(X)$  is an isomorphism.

Similar definitions apply for cosimplicial objects.

**Example 1.1.4.3** Let  $X \in \mathbf{sC}$  be a simplicial object. Our  $X$  is 0-skeletal if and only if it is *constant*. It is 0-coskeletal if and only if it is determined by  $X_0$  via the formula

$$X_m = X_0^{\times(m+1)}.$$

**Example 1.1.4.4** The standard  $n$ -simplex  $\Delta^n$  is  $n$ -skeletal. For a simplicial set  $X$ , the  $n$ -skeleton  $\mathrm{sk}_n(X)$  is the colimit of the  $m$ -simplices of  $X$  with  $m \leq n$ :

$$\mathrm{sk}_n(X) = \operatorname{colim}_{[m] \in (\Delta_{\leq n})/X} \Delta^m.$$

(Exercise 1.1.2.)

**Example 1.1.4.5** If  $X$  is a simplicial set, then we have a formula for the  $m$ -simplices of the  $n$ -coskeleton:

$$\mathrm{ck}_n(X)_m = \operatorname{Mor}_{\mathbf{sSet}}(\mathrm{sk}_n(\Delta^m), X).$$

**Example 1.1.4.6** The nerve of any small category is 2-coskeletal (Exercise 1.1.3).

### 1.1.5 Boundaries & horns

**Definition 1.1.5.1** Let  $X$  be a simplicial set. A *simplicial subset*  $Y \subseteq X$  is a choice of a subset  $Y_n \subseteq X_n$  for each  $n \geq 0$  such that for any map  $\phi: [m] \rightarrow [n]$  in  $\Delta$ , the induced map  $X_n \rightarrow X_m$  carries  $Y_n$  to  $Y_m$ .

We are particularly interested here in simplicial subsets of the simplicial set  $\Delta^n$ .

**Notation 1.1.5.2** Let  $0 \leq i_0 < i_1 < \cdots < i_k \leq n$  be integers. Then we write

$$\Delta^{\{i_0, \dots, i_k\}} \subseteq \Delta^n$$

for the corresponding simplicial subset of  $\Delta^n$ . This simplicial subset is itself a  $k$ -simplex.

Families of simplicial subsets of a simplicial set  $X$  can be intersected or unioned, just as with subsets of a set.

**Definition 1.1.5.3** Let  $n \geq 0$  be an integer. For every integer  $0 \leq i \leq n$ , the  $i$ -th *face* is the simplicial subset

$$\Delta^{\hat{i}} := \Delta^{\{0, \dots, i-1, i+1, \dots, n\}} \subset \Delta^n.$$

This is the unique  $(n-1)$ -simplex of  $\Delta^n$  that does not contain the vertex  $\Delta^{\{i\}}$ .

The *boundary* of the  $n$ -simplex is the union of all the faces of  $\Delta^n$ :

$$\partial\Delta^n := \bigcup_{0 \leq i \leq n} \Delta^i \subset \Delta^n.$$

For every integer  $0 \leq k \leq n$ , the  $k$ -th *horn* is the union of all but the  $k$ -th face of  $\Delta^n$ :

$$\Lambda_k^n := \bigcup_{0 \leq i \leq n, i \neq k} \Delta^i \subset \Delta^n.$$

This is the union of all the faces of  $\Delta^n$  that contain the vertex  $\Delta^{\{k\}}$ .

Equivalently,  $\partial\Delta^n$  can be described as the  $(n-1)$ -skeleton of the  $n$ -simplex:

$$\partial\Delta^n = \text{sk}_{n-1}(\Delta^n).$$

Thus

$$\text{Mor}_{\mathbf{sSet}}(\partial\Delta^n, X) = \text{ck}_{n-1}(X)_n.$$

### 1.1.6 Geometric realization

We have seen that every simplicial set is the colimit of its simplices.

### 1.1.7 Higher groupoids & higher categories

Let's start with  $(2, 1)$ -categories. These are categories with the property that between two objects  $x$  and  $y$ , we have a *groupoid* of maps  $x \rightarrow y$ . Accordingly, between two maps  $f, g: x \rightarrow y$  we have a set of isomorphisms  $\text{Isom}(f, g)$ .

### 1.1.8 Fibrations

#### Exercises

- 1.1.1 Use the Yoneda lemma to show that for any small category  $A$ , the left Kan extension of the Yoneda embedding  $A \hookrightarrow \text{Fun}(A^{op}, \mathbf{Set})$  along itself is the identity functor.
- 1.1.2 We have seen that every simplicial set  $X$  is the colimit of its simplices. Now show that  $X$  is  $n$ -skeletal if and only if the canonical map

$$\text{colim}_{[m] \in \Delta_{\leq n}/X} \Delta^m \rightarrow X$$

is an isomorphism.

- 1.1.3 Show that the composition of the nerve functor  $N: \mathbf{Cat} \rightarrow \mathbf{sSet}$  with the restriction  $\mathbf{sSet} \rightarrow \mathbf{s}_{\leq 2}\mathbf{Set}$  is fully faithful. Conclude that the nerve of every small category is 2-coskeletal.
